

Silurian Algal Reef Crest in Gotland

R. Riding and N. Watts

Department of Geology, University College, Cardiff CF1 1XL, U.K.

In the Wenlock (middle Silurian) of the north-west coast of Gotland (Fig. 1) reefs occur in the Höglint Beds near the top of a shallowing-up marine sequence [1] and show internal upward zonation from relatively weak tabulate-dominated bioherms to stronger stromatoporoid-frame bioherms [2]. The algal zone caps this 50 m+ sequence and forms a thin (generally 0.3–0.6 m, max. 3 m) band in the upper Höglint traceable for several hundred metres at localities in and around Visby.

At Korpklint and Gutevågen it is a thin, discontinuous biostromal unit capping the stromatoporoid-dominated reef sub-facies. Gålberget, an intermediate location immediately north of Visby shows current-active, well-sorted, coarse bioclastic grainstones probably laterally equivalent to the algal zone. The algal zone immediately underlies a disconformity which truncates the reef sequence as a whole and juxtaposes the lagoonal Tofta Beds (Fig. 2).

Dense in-place growths of *Solenopora* and *Hedstroemia* constitute 30–65% of the rock volume. *Solenopora* (an extinct relative of the crustose coralline red algae which dominate Recent algal ridges) ranges in form from small stubby digitate clusters to encrusting masses 0.45 m high and 1.75 m across. A thin arcuate form, unusual for *Solenopora*, also occurs as leaflike sheets,

4 mm thick and 5 cm across, but is only present in minor amounts. *Parachartetes*, another solenoporacean, forms a small proportion of the rock volume. *Hedstroemia* resembles the Recent cyanophyte *Rivularia*. It occurs as small rounded growths amalgamated into crusts up to 30 cm thick.

These two principal algal components overgrew one another to form an interlocking rigid framework which was strengthened and enlarged by additional attached organisms, mainly bryozoans and crusts of *Rostkjerella* (problematicum) and *Wetheredella* (? foraminifer). These usually occur on the tops and sides of the main builders. Small gastropods and serpulids are minor additional components, together with attached crinoid stems. The stromatoporoids and tabulate and rugose corals which dominate the lower reef zones are relatively uncommon in the algal zone.

This association of mutually attached bryozoans, ? foraminifers, gastropods and serpulids within an algal framework closely resembles that of modern algal ridges and reefs [3, 4] and the proportion of in-place skeletons to matrix and pores (3:2 in Gotland) is also similar. The digitate and rounded forms of the main components in Gotland differ from the essentially

Fig. 2. Upper Höglint and lower Tofta sequence at Gutevågen, Visby. Wavy lines mark erosional breaks

laminar forms of crustose corallines and *Millepora* in Bermudan cup reefs [3] but the tightness of the resulting framework is similar, and Caribbean algal ridges have both sheet-like and stubbly-branched crustose corallines [4, 5].

The interskeletal areas in the Höglint reef crest show crudely graded fills with grain size directly related to pore size, reflecting the progressive reduction and eventual plugging of cavities. As in Bermudan cup reefs [3] micritic sediment was pumped into the algal frame and remained trapped in the network of small cavities despite high-energy conditions outside.

Early micritic cement is an important interstitial component and would have added considerably to the strength of the skeletal framework. Even so, occasional displaced blocks, in which several generations of submarine and freshwater sediment and cement infills allow the relative time of fracturing and movement to be determined, show that water movement was sufficiently powerful to break the frame locally after early cementation, as also happens in the surf zones of Recent reefs.

Exposure of this shallow algal reef crest soon after deposition is reflected by extensive relatively early vadose dissolution and cementation effects within it, and by the
